

Master Thesis:

Design and Development of a Fog Service  
Orchestration Engine for Smart Factories

Master Thesis  
from

Markus Paeschke

Supervisor: Prof. Dr.-Ing. Thomas Magedanz  
Dr.-Ing. Alexander Willner  
Mathias Brito

Markus Paeschke  
Trachtenbrodtstr. 32  
10409 Berlin

I hereby declare that the following thesis “Design and Development of a Fog Service Orchestration Engine for Smart Factories” has been written only by the undersigned and without any assistance from third parties.

Furthermore, I confirm that no sources have been used in the preparation of this thesis other than those indicated in the thesis itself.

Berlin, March 3, 2017

## Introduction

### 1.1 Background and Motivation

The Internet of Things (IoT) is one of the biggest topic in the recent years. Companies with a focus in that area have an enormous market growth with plenty of new opportunities, use cases, technologies, services and devices. Bain & Company predicts an annual revenue of \$450 billion for companies who selling hardware, software and comprehensive solutions in the IoT context by 2020.[BCJ<sup>+</sup>16] In order to limit the vast area of IoT, more and more standards are defined and subtopics established. The European Research Cluster on the Internet of Things (IERC) devided them into eight categories: Smart Cities, Smart Healthcare, Smart Transport and Smart Industry also known as Industry 4.0 to mention only a few. All of them are well connected, for example a Smart Factory, which is a part of the Smart Industry, can get a delivery from a self driving truck (Smart Transport) which navigates through a Smart City to get to the factory. Such information networks are one of the main goals of IoT. In the Industry 4.0 for example multiple Smart Factories should be interconnect into a distributed and autonomous value chain. Also the automation in a single factory will be increased which helps to have a more flexible and efficient production process. Currently a factory has a high degree of automation, but due to a lack of intelligence and communication between the machines and the underlying system, they can not react to changing requirements or unexpected situations. One solution to achieve that are Cyber-Physical Systems (CPSs). These are virtual systems which are connected with embedded systems to monitor and control physical processes.[Lee08] A normal Cyber Systems (CSs) is passive, means it could not interact with the physical world, with the appearance of CPSs things can communicate so the system has significantly more intelligence in sensors and actuators.[Poo10]

Cloud Computing was one of the prime topic in the recent years. It changed from a monolithic to more distributed multicloud architecture. With the appearance of the Internet of Things (IoT) and related architectures like Fog Computing the cloud moves away from centralized data centers to the edge of the underlying network [1]. Such a network can have thousands of nodes with multiple sensors, machines or smart components connected to them. An "intermediate layer between the IoT environment and the Cloud" [2] enables a lot of new possibilities like pre-computation and storage of gathered data, which reduces traffic and resource overhead in the cloud, it keeps sensitive data on-premise [2] and enables real-time applications to take decisions based on analytics running near the device and a lower latency

[3]. On the other hand there are also a lot of challenges in these highly heterogeneous and hybrid environment. As an example in some scenarios multiple low power devices have to interact with each other, lossy signals and short range radio technologies are widely used and nodes can appear and disappear frequently [3]. Especially the last case is elaborated because the underlying system has to handle that. Furthermore the required applications running on these nodes can be change commonly and have to be deployed and removed in a dynamical way. Virtualization with Virtual Machines (VMs) is a common approach in Cloud systems to provide elasticity of large-scale shared resources[4]. A more lightweight, less resource and time consuming solution is container virtualization. "Furthermore, they are flexible tools for packaging, delivering and orchestration software infrastructure services as well as application"[4]. Orchestration tools like Kubernetes[5], Docker Swarm[6] or CoreOS[7] which deploy, scale and manage containers to clusters of hosts have become established in the last years. Moving this technology over to the IoT area many challenges can be solved. Dynamically deployed applications at the edge of a network can store and preprocesses gather data even if a node have no connection to the cloud because of lossy signals. Traffic can be reduced by only transmitting aggregated data back to the cloud. More often small low-power devices with limited computational power are be used as IoT nodes which also profit rather from lightweight container solutions than from resource consuming VMs. This paper shows the capabilities of container orchestration for the IoT and Smart Factories using the Open Baton framework. Therefor a plugin will be created which can orchestrate Docker containers based on functional and non-functional constraints to fog nodes.

## **1.2 Problem Statement**

## Chapter 2

# State of the art

This chapter will give an overview into the background and concepts of this thesis. In the first section the Internet of Things and related subtopics like Smart Factories and Smart Cities are considered. Cyber Physical Systems, which are important for the development of Smart Factories are also covered in this section. Virtualization in general is the main topic of the second section. First we dive into the area of Virtual Machines, followed by Container Virtualization. Both are related to each other and sharing some basic ideas. Container Orchestration as an own subsection shows some possibilities of Container Virtualization. The last subsection Network Function Virtualization concludes with an introduction into the virtualization of network node functions to create communication services.

### 2.1 Internet of Things

The IoT has been a subject of great media- and economically growth in the recent years. In the year 2008 the number of devices which are connected to the Internet was higher than the human population.[Eva11, cf.] Cisco Internet Business Solutions Group predicted that the number will grow up to 50 billion in 2020, this equates to around 6 devices per person.[Eva11, cf.] Most of today's interactions are Human-to-Human (H2H) or Human-to-Machine (H2M) communication. The IoT on the other hand aims for the Machine-to-Machine (M2M) communication. This allows every physical device to be interconnected and to communicate with each other. These devices are also called "Smart Devices". Creating a network where all physical objects and people are connected via software is one primary goal of the IoT.[RD15, cf.][KKL13, cf.] When objects are able to capture and monitor their environment, a network can perceive external stimuli and respond to them.[cf. Itu05, p. 40] Therefore a new dimension of information and communication technology will be created, where users have access to everything at any time, everywhere. In addition to smart devices, subcategories are also emerging from the IoT which, in addition to the physical devices, also describe technologies such as protocols and infrastructures. The "Smart Home" has been a prominent topic in media and business for many years. Smart City or Industrie 4.0 are also becoming established and are increasingly popular. But the Internet started with the appearance of bar codes and Radio Frequency Identification (RFID) chips.[KKL13, cf.] The second step, which is more or less the current situation, sensors, physical devices, technical devices, data and software are connected to each other.[KKL13, cf.] This was achieved, in particular, by

cloud computing, which provides the highly efficient memory and computing power that is indispensable for such networks.[RD15, cf.] The next step could be a "Cognitive Internet of Things", which enables easier object and data reuse across application areas, for example through interoperable solutions, high-speed Internet connections and a semantic information distribution.[KKL13, cf.] Just as the omnipresent information processing in everyday life, also known as "Ubiquitous Computing", which was first mentioned in the "The Computer for the 21st Century"[Wei91, cf.] by Marks Weiser, it will take some time until it is ubiquitous.

### 2.1.1 Industry 4.0 and Smart Factories

The industry as an changing environment is currently in the state of the so called "fourth industrial revolution". The first industrial revolution was driven by steam powered machines. Mass production and division of labor was the primary improvement of the second industrial revolution, whereas the third revolution was characterized by using electronics and the integration of Information Technology (IT) into manufacturing processes.[cf. LPS16, p. 1] In the recent years the size, cost and power consumption of chipsets are reduced which made it possible to embed sensors into devices and machines much easier and cheaper.[cf. BHSW16, p. 1] The Industry 4.0 is the fourth step in this evolution and was first mentioned with the German term "Industrie 4.0" at the Hannover Fair in 2011.[cf. LPS16, p. 1] "Industrie 4.0 is a collective term for technologies and concepts of value chain organization." [cf. HPO15, p. 11]

Significantly higher productivity, efficiency, and self-managing production processes where everything from machines up to goods can communicate and cooperate with each other directly are the visions of the Industry 4.0.[Lyd16, cf.] It also aims for an intelligent connection between different companies and units. Autonomous production and logistics processes creating a real-time lean manufacturing ecosystem that is more efficient and flexible.[Lyd16, cf.] "This will facilitate smart value-creation chains that include all of the life-cycle phases of the product from the initial product idea, development, production, use, and maintenance to recycling." [Lyd16] At the end, the system can use customer wishes in every step in the process to be flexible and responsive.[Lyd16, cf.]

	Cyber-Physical Systems	Internet of Things	Internet of Services	Smart Factory
Interoperability	X	X	X	X
Virtualization	X	-	-	X
Decentralization	X	-	-	X
Real-Time Capability	-	-	-	X
Service Orientation	-	-	X	-
Modularity	-	-	X	-

Table 1: Design principles of each Industry 4.0 component.[cf. HPO15, p. 11]

Table 1 shows the six design principles which can be from the Industrie 4.0 components. They can help companies to identify and implement Industry 4.0 scenarios.[cf. HPO15, p. 11]

1. *Interoperability* CPS of various manufacturers are connected with each other. Standards will be the key success factor in this area.[cf. HPO15, p. 11]

2. *Virtualization* CPS are able to monitor physical processes via sensors. The resulting data is linked to virtual plant and simulation models. These models are virtual copies of physical world entities.[cf. HPO15, p. 11]
3. *Decentralization* CPS are able to make decisions on their own, for example when RFID chips send the necessary working steps to the machine. Only in cases of failure the systems delegate task to a higher level.[cf. HPO15, p. 11]
4. *Real-Time Capability* Data has to be collected and analyzed in real time and the status of the plant is permanently tracked and analyzed. This enables the CPS to react to a failure of a machine and can reroute the products to another machine.[cf. HPO15, p. 11]
5. *Service Orientation* CPS are available over the Internet of Services (IoS) and can be offered both internally and across company borders to different participants. The manufacturing process can be composed based on specific customer requirements.[cf. HPO15, p. 11]
6. *Modularity* The system is able to be adjusted in case of seasonal fluctuations or changed product characteristics, by replacing or expanding individual modules.[cf. HPO15, p. 11]

Another important aspect of Industry 4.0 is the implementation of process automation with the focused on three distinct aspects. Starting with the vertical integration, which contains the connection and communication of subsystems within the factory enables flexible and adaptable manufacturing systems.[cf. Vbw14, p. 7 ff.] The horizontal integration, as the second aspect, enables technical processes to be integrated in cross-company business processes and to be synchronized in real time through multiple participants to optimize value chain outputs.[cf. Vbw14, p. 7 ff.] Finally end-to-end engineering, planning, and process control for each step in the production process.[Lyd16, cf.]

Figure 1: Horizontal vs. Vertical Integration. Adapted from: [Jur13]

Figure 1 illustrates this concept. The left side shows the whole production process over company boundaries on the horizontal scale, as well as the industry value chain on the vertical scale which is specific for each company. On the right side there is an exemplary industry value chain which starts with the raw materials and ends with the sale of the product to illustrate an more specific example of the vertical integration. From a technical site this means each machine in a factory has exactly to know what they have to do. The underlying system has to be modular and move away from a monolithic centralized system, to a decentralized system which is located locally near the machines himself. The communication path between them have to grow shorter. The machines have to be self organized and should communicate between each other even if the core system is not reachable because of lossy signals or other connection issues. If this can be achieved there will be an highly flexible, individualized and resource friendly mass production, which can be cheaper, faster and can have a much higher fault tolerance.

### 2.1.2 Cyber Physical Systems

As we already now, in smart factories every physical device is connected to each other. Everything can be captured and monitored in each step of a production process. With CPSs every physical entity has a digital representation in the virtual system.[cf. Poo10, p. 1363] Before a CS was passive, which means it has no communication between the physical and the virtual world.[cf. Poo10, p. 1364] While new technologies in the physical world, like new materials, hardware and energy, are developed, the technologies in the virtual worlds are also being improved, for example through the use of new protocols, networking, storage and computing technologies.[cf. Poo10, p. 1364] This adds more intelligence in such systems, as well as a much more flexible and modular structure. A CPS can organize production automatically and autonomously, which eliminate the need of having a central process control.[? , cf.] Thereby the system can handle lossy signals and short range radio technologies, which are widely used in such a context.[YMSG<sup>+</sup>14, cf.] [write more](#)

### 2.1.3 Fog Computing

[write more](#) —————

## 2.2 Virtualization

According to the National Institute of Standards and Technology (NIST) the definition of virtualization is: "Virtualization is the simulation of the software and/or hardware upon which other software runs. This simulated environment is called a virtual machine (VM)."[SSH11]. This means a Virtual Machine (VM), also referred as guest system, can be executed in a real system, which is referred as host system. A VM has its own Operating System (OS) which is completely isolated from the other VMs and the host system.[cf. CMF<sup>+</sup>16, p. 2] Basically there are two types of virtualization: Process virtualization where the virtualizing software also known as Virtual Machine Monitor (VMM) is executed by the host OS and only an application will be executed inside the guest OS and on the other side there is the the system virtualization where the whole OS as well as the application are running inside the virtualizing

software. Figure 2 illustrate both concepts. Examples for process virtualization could be the Java Virtual Machine (JVM)<sup>1</sup>, the .Net framework<sup>2</sup> or Docker<sup>3</sup>, where VMWare<sup>4</sup>, Oracle Virtual Box<sup>5</sup>, XEN<sup>6</sup> or Microsoft Hyper-V<sup>7</sup> are only some examples for system virtualization. The benefits of all virtualization techniques are the rapid provisioning of resources which could be Random Access Memory (RAM), disk storage, computation power or network bandwidth. Beside that, no human interaction is necessary during the provisioning process. Elasticity which scales a system in a cost-efficient manner in both directions, up and down. Customer as well as the provider profit from such a system. Security based on the isolation of the VMs is another huge benefit. Different processes can not interfere with each other and the data of a single user can not be accessed by other users of the same hardware. A challenge despite all the mentioned benefits is the performance. Running VMs increases the overhead and reduces the overall performance of a system. Therefore the specific use case have to consider these behavior.

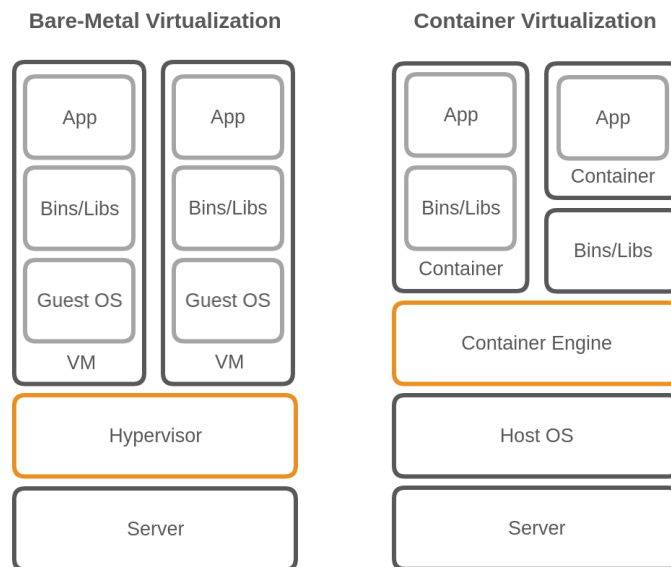

Figure 2: Structure bare-metal virtualization vs. container virtualization. Adapted from: [Gal15, p. 2]

### 2.2.1 Virtual Machines

VMs are the core virtualization mechanism in cloud computing. There are also two different designs for hardware virtualization. The first and more popular type for cloud computing is the *bare-metal virtualization*. It needs only a basic OS to schedule VMs. The hypervisor runs directly on the hardware of the machine without any host OS in between. This is more efficient, but requires special device drivers to be executed. The other type is the *hosted*

<sup>1</sup><https://www.java.com>

<sup>2</sup><https://www.microsoft.com/net>

<sup>3</sup><https://www.docker.com>

<sup>4</sup><http://www.vmware.com>

<sup>5</sup><https://www.virtualbox.org>

<sup>6</sup><https://www.xenproject.org>

<sup>7</sup><https://www.microsoft.com/de-de/cloud-platform/server-virtualization>

*virtualization*. Unlike the first type the VMM run as a host OS process and the VMs as a process supported by the VMM. No special drivers are needed for these type of virtualization, but by comparison the overhead is much bigger. For both types, the performance limitation remains. Each VM need a full guest OS image in addition to binaries and libraries which are necessary for the application to be executed.[cf. PL15, p. 381] If only a single application, which only needs a few binaries and libraries, is needed to be virtualized, VMs are too bloated.

## 2.2.2 Container Virtualization

Container virtualization which is also known as Operating System-level virtualization, is the second virtualization mechanism. It based on fast and lightweight process virtualization to encapsulate an entire application with its dependencies into a ready-to-deploy virtual container.[cf. TRA15, p. 72] Such a container can be executed on the host OS which allows an application to run as a sandboxed user-space instance.[cf. AHA<sup>+</sup>16, p. 1] All containers share a single OS kernel, so the isolation supposed to be weaker compared to hypervisor based virtualization.[cf. CMF<sup>+</sup>16, p. 2] Compared to VMs, the number of containers on the same physical host can be much higher, because the overhead of a full OS virtualization is eliminated.[cf. CMF<sup>+</sup>16, p. 2]

### Linux Containers

When we talk about container virtualization nowadays, Docker have to become one of the most famous tools out there. It based on Linux Containers (LXC)<sup>8</sup> a technology which uses kernel mechanisms like *namespaces* or *cgroups* to isolate processes on a shared OS.[cf. PL15, p. 381] Namespaces for example are used to isolate groups of processes whereas cgroups are used to manage and limit resources access just like restricting the memory, disc space or Central Processing Unit (CPU) usage.[cf. PL15, p. 381] "The goal of LXC is to create an environment as close as possible to a standard Linux installation but without the need for a separate kernel." [TRA15, p. 72] There are several other container virtualization tools out there like OpenVZ<sup>9</sup> or Linux-VServer<sup>10</sup>. In contrast to them, an advantage of LXC is that it runs on an unmodified Linux kernel. This means that LXC can be executed in most of the popular Linux distributions these days.

### Docker

As mentioned before, Docker based on LXC. This allows the Docker Engine to build, deploy and run containers in an easy and customizable way. Similar to VMs, containers are executed from images. A mayor benefit of Docker is the fact, that Docker images can be combined like build blocks. Each image can build on top of another. Figure 3 illustrates the concept for the image of the pretty famous Django<sup>11</sup> web framework. In that case, the Django image, which is the resulting image, based on the Python 3.4 image which again based on the Debian Jessie image. All of them are read-only, but Docker adds a writeable layer, also known as *container*

---

<sup>8</sup><https://linuxcontainers.org/>

<sup>9</sup>[https://openvz.org/Main\\_Page](https://openvz.org/Main_Page)

<sup>10</sup><http://www.linux-vserver.org>

<sup>11</sup><https://www.djangoproject.com/>

*layer*, on top of the images as soon as the container will be created. File system operations such as creating new files, modifying or deleting existing files are written directly to these layer.[Docb, cf.] The other images don't get involved. These chaining mechanism of images allows Docker to ease the use of dependencies and administrative overhead.

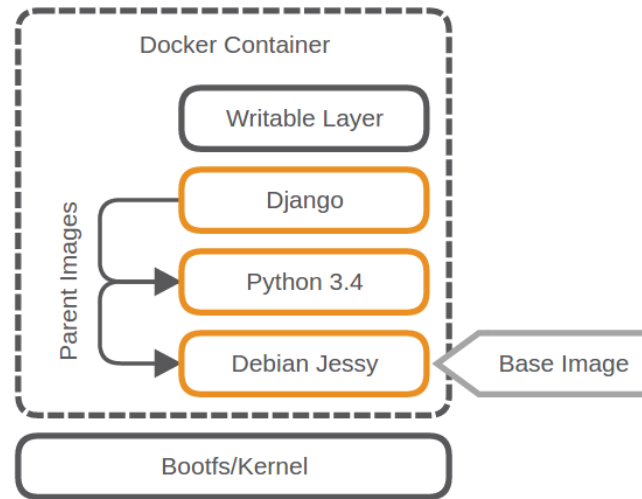

Figure 3: Docker container structure.

Beside that, Docker is splitted up in several components, such as the Docker Engine, the Docker Registries and Docker Compose to mention only a few. The Docker Engine is a client-server application which can be distinguished by the Docker client, a Representational State Transfer (REST) Application Programming Interface (API) and the Docker server. Latter is a daemon process which "creates and manages Docker objects, such as images, containers, networks, and data volumes"[Doca]. The client is a Command Line Interface (CLI), which interact via a REST API with the daemon.[Doca, cf.]

Another component, the Docker Registry, is basically a library of Docker images. They can be public or private available, as well as on the same machine like the Docker daemon or an external server.[Doca, cf.] The most popular one is the official Docker Hub<sup>12</sup>. There is also an Docker Store<sup>13</sup>, where customers can buy and sell trusted and enterprise ready containers and plugins. With the Docker client it is pretty easy to *search* for new containers and to *pull* containers from or *push* containers to a specific repository.

With Docker Compose multiple Docker Containers can be executed as a single application. Therefore YAML compose file will be used to configure and combine the services. For example the already mentioned Django image can be executed and linked together with a MongoDB<sup>14</sup> images. The main benefit is the ease of configure dependencies between several containers and configuration steps. These concept is similar to deployment tools like Vagrant<sup>15</sup>, Ansible<sup>16</sup> or Puppet<sup>17</sup>.

<sup>12</sup><https://hub.docker.com>

<sup>13</sup><https://store.docker.com>

<sup>14</sup><https://www.mongodb.com>

<sup>15</sup><https://www.vagrantup.com>

<sup>16</sup><https://www.ansible.com>

<sup>17</sup><https://puppet.com>

A major benefit of Docker is that the execution environment of an application is completely the same on a local machine as on the production environment.[cf. Gal15, p. 2] There is no need to do things differently when switching from a development environment like a local machine, to a production environment like a server.[cf. Gal15, p. 2]

### 2.2.3 Container Orchestration

Containers by itself helps to develop and deploy applications, but containers release their full potential only when they are used together with an orchestration engine. Before orchestration engines, the deployment of an application or service was realized via Continuous Integration (CI) and deployment tools like Vagrant or Ansible. Deployment scripts or plans was created and be executed every time an application changed or should be scaled up on a new machine. This was less flexible and error-prone. Orchestration engines cover these needs by automatically choosing new machines, deploying containers, handle the lifecycle of them and monitor the system. These flexibility enables a new level of abstraction and automatization of deployment. There are a bunch of orchestration engines out there. For Docker Kubernetes and Docker Swarm are the most popular once at the moment.

#### Kubernetes

Kubernetes is an open source container cluster manager which was released 2014 by Google. It is "a platform for automating deployment, scaling, and operations"[Gra15, p. 1] of containers. Therefore a cluster of containers can be created and managed. The system can for example schedule on which node a container should be executed, handle node failures, can scale the cluster by adding or removing nodes or enable rolling updates.[Gra15, p. 5 f.]

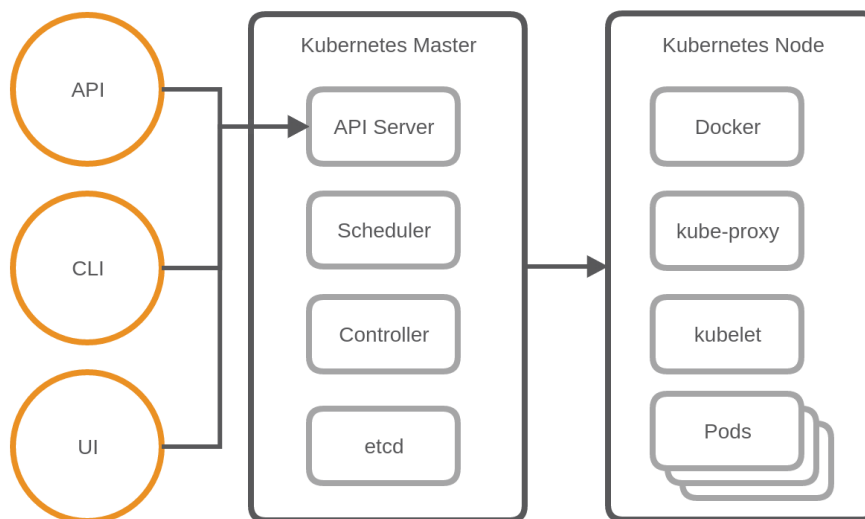

Figure 4: Kubernetes architecture. Adapted from: [MSV16]

Figure 4 illustrates the basic architecture of Kubernetes. The user can interact with the Kubernetes system via a CLI, an User Interface (UI) or a third party application, over a REST API to the Kubernetes Master or more specifically the API Server in the master. The

master himself controls the one or multiple nodes, monitor the system, schedule resources or pull new images from the repository, to name only a few tasks. Each node has a two way communication with the master via a kubelet. In addition each node has the services necessary to run container applications like Docker. Furthermore Kubernetes can combine one or multiple containers into one so called Pod.[cf. Mul16, p. 7] "Pods are always co-located and co-scheduled, and run in a shared context." [Kub16c] One node again can execute multiple Pods. Pods are only temporary grouped containers with a non-stable IP address. After a Pod is destroyed it can never be resurrected. Pods can also share functionality to other Pods inside a Kubernetes cluster. A logical set of Pods and the access policy of them is called a Kubernetes service. Such a service can abstract multiple Pod replicas and manage them. A frontend which have access to the service do not care about changes in the service. Any change, be it a down scale or an up scale of the system, remains unseen for the frontend. They are exposed through internal or external endpoints to the users or the cluster.[cf. MSV16, p. 11] Labels can be used to organize and to select subsets of Kubernetes Objects, such as Pods or Services.[Kub16b, cf.] They are simply key/value pairs which and should be meaningful and relevant to users, but do not imply semantics to the core system.[Kub16b, cf.] The kube-proxy is a network proxy and load balancer which is accessible from the outside of the system via a Kubernetes service.[cf. Mul16, p. 7] "Each node and can do simple TCP,UDP stream forwarding or round robin TCP,UDP forwarding across a set of backends." [Kub16a] The Replication Controller is one of the mayor controllers in a Kubernetes System. It ensures that a specified number of pod replicas are running and available at any time.[Kub16d, cf.] If for example one node disappear because of connection issues, the Repliation Controller will start a new one. If the disappeared node is available back again it will kill a node. These functionality increases the stability, the availability and the scalability of the system in an autonomous manner. The last important component in Kubernetes are rolling updates. With rolling updates the system can update one pod at a time, rather than taking down the entire service and update the whole system.??cf.]Kubernetes:rolling-updates:2016 This also increases the stability and availability of the system and eases the managing of container clusters.

## 2.2.4 Network Function Virtualization

Network Function Virtualistion (NFV) is an architectural framework to provide Network Functions (NFs) through software virtualization techniques to a single piece of hardware instead of multiple different devices for each function, e.g. router, firewall, storage, switch, etc.[cf. ETS13, p. 8] "These NFs are referred as Virtual Network Functions (VNFs)." [ETS13, p. 8] write more —————
